Abstract

Bernoulli sets—random approximate sets with independent, element-wise errors parameterized by false positive and false negative rates—are closed under set-theoretic composition. We derive closed-form error rates for complement, union, intersection, and set difference, showing that every such operation on Bernoulli sets yields a (possibly higher-order) Bernoulli set whose error rates are computable functions of the operand rates and set cardinalities. The resulting structure is monoidal under union and intersection, supports exact computation of relational predicates (subset and equality probabilities), and admits an interval arithmetic extension that propagates uncertain rate parameters through set operations with guaranteed bounds. These results build on the Bernoulli set model introduced in a companion paper [4], which establishes the axioms, error-count distributions, and asymptotic limits assumed here.

1 Introduction

The Bernoulli set model [4] provides a probabilistic framework for *random approximate sets*—sets that approximate an objective set with independent, element-wise errors parameterized by false positive and false negative rates. That companion paper establishes the axioms, derives the binomial distributions of error counts, and develops the asymptotic normal limits and confidence intervals for the error rates.

This paper addresses the *compositional* question: what happens when Bernoulli sets are combined through set-theoretic operations? Practical systems rarely use a single approximate set in isolation. Encrypted search indexes, database query planners, and distributed systems routinely compose approximate sets through union, intersection, complement, and difference. Without a compositional algebra, each new combination requires a bespoke error analysis.

Contribution. We show that Bernoulli sets are *closed* under set-theoretic composition: every operation on Bernoulli sets yields a (possibly higher-order) Bernoulli set whose error rates are closed-form functions of the operand rates and set cardinalities. Specifically, we derive:

1. closed-form error rates for complement, union, intersection, and set difference, together with the monoidal structure they induce,
2. exact formulas for the relational predicates (subset and equality probabilities) on Bernoulli sets, and
3. an interval arithmetic extension that propagates uncertain rates through set operations, yielding guaranteed bounds on output error rates.

Organization. Section 2 restates the definitions and results from [4] needed in this paper. Section 3 derives error rates for all four set-theoretic operations and establishes closure properties. Section 4 treats relational predicates (subset, equality) on Bernoulli sets. Section 5 develops interval arithmetic for uncertain rate parameters.

2 Preliminaries

We briefly restate the elements of the Bernoulli set model [4] needed in this paper.

2.1 Bernoulli set model

Let U be a finite universal set with $u = |U|$, and let $A \subseteq U$ be an objective set. A *Bernoulli set* $\tilde{A}$ is a random approximate set of A governed by two axioms.

Axiom 1 (Element-wise independence [4, Axiom 1]). *For all distinct $x, y \in U$, the error events at x and y are mutually independent. Furthermore, within each partition block B_i (definition 2.1), the error indicators $\{\mathbf{1}_{\tilde{A}}(x) : x \in B_i\}$ are identically distributed.*

Axiom 2 (Conditional independence of block error rates [4, Axiom 2]). *Given the objective set R , the random error rates $\alpha_1, \dots, \alpha_n$ for the respective partition blocks $B_1, \dots, B_n$ are mutually independent.*

The Bernoulli set $\tilde{A}$ is parameterized by its expected false positive rate ε and expected true positive rate τ , writing $\tilde{X}[\varepsilon][\tau]$. The complementary rates are $\omega = 1 - \tau$ (FNR) and $\eta = 1 - \varepsilon$ (TNR).

Proposition 2.1 (Element-level error probabilities [4, Prop. 1]). *By axiom 1, for any single element $x \notin A$, $P(\mathbf{1}_{\tilde{A}}(x) = 1) = \varepsilon$, and for $x \in A$, $P(\mathbf{1}_{\tilde{A}}(x) = 1) = \tau$.*

Definition 2.1 (Model order [4, Def. 3]). *The order of a Bernoulli set model is the number of partition blocks n . A zeroth-order model ($n = 0$) is exact. A first-order model ($n = 1$) assigns a single error rate (symmetric channel). A second-order model ($n = 2$) distinguishes positives from negatives with rates τ and ε . In general, an n -th order model partitions U into n blocks, each with its own error rate.*

2.2 Distributions and asymptotic limits

The number of false positives given n negatives is binomially distributed: $FP_n \sim \text{Bin}(n, \varepsilon)$. Similarly, the number of false negatives given p positives satisfies $FN_p \sim \text{Bin}(p, \omega)$.

The random false positive rate $\alpha_n = FP_n/n$ converges in distribution to

$$\alpha_n \xrightarrow{d} \mathcal{N}(\varepsilon, \varepsilon(1 - \varepsilon)/n), \quad (2.1)$$

and the random true positive rate $\mathcal{T}_p$ converges to $\mathcal{N}(\tau, \tau(1 - \tau)/p)$. Asymptotic $\gamma \cdot 100\%$ confidence intervals for the false positive rate and true positive rate are respectively

$$\varepsilon \pm \sqrt{\frac{\varepsilon(1 - \varepsilon)}{n}} \Phi^{-1}\left(\frac{1 + \gamma}{2}\right) \quad (2.2)$$

and

$$\tau \pm \sqrt{\frac{\tau(1 - \tau)}{p}} \Phi^{-1}\left(\frac{1 + \gamma}{2}\right), \quad (2.3)$$

where Φ^{-1} is the inverse CDF of the standard normal. See [4] for proofs.

3 Set-theoretic operations

In this section, we derive the error rates of Bernoulli sets under the standard set-theoretic operations: complement, union, intersection, and set difference. Throughout, we assume that the Bernoulli sets $\tilde{A}_1$ and $\tilde{A}_2$ approximate objective sets A_1 and A_2 respectively over a common finite universal set U with cardinality $u = |U|$. The Bernoulli set $\tilde{A}_i$ has false positive rate ε_i and false negative rate ω_i for $i \in \{1, 2\}$. By the axioms of the Bernoulli set model, the membership errors of distinct elements are independent.

Assumption 1 (Cross-set independence). *The Bernoulli sets $\tilde{A}_1$ and $\tilde{A}_2$ are constructed using independent randomness: for all $x \in U$, the error indicators $\mathbf{1}_{\tilde{A}_1}(x) \neq \mathbf{1}_{A_1}(x)$ and $\mathbf{1}_{\tilde{A}_2}(x) \neq \mathbf{1}_{A_2}(x)$ are independent.*

3.1 Complement

The complement operation exchanges the roles of positives and negatives. Accordingly, false positives become false negatives and vice versa.

Theorem 3.1 (Complement error rates). *Let $\tilde{A}$ be a Bernoulli set approximating A with false positive rate ε and false negative rate ω . Then the complement $\bar{\tilde{A}}$ is a Bernoulli set approximating A^c with false positive rate ω and false negative rate ε .*

Proof. The positives of A^c are exactly the negatives of A , and the negatives of A^c are exactly the positives of A .

A false positive of $\tilde{A}$ with respect to A^c occurs when an element $x \notin A^c$ (i.e., $x \in A$) satisfies $x \in \tilde{A}$, which holds if and only if $x \notin \tilde{A}$. Since $x \in A$, the event $x \notin \tilde{A}$ is a false negative of $\tilde{A}$, which occurs with probability ω . Therefore the false positive rate of $\tilde{A}$ with respect to A^c is ω .

A false negative of $\tilde{A}$ with respect to A^c occurs when an element $x \in A^c$ (i.e., $x \notin A$) satisfies $x \notin \tilde{A}$, which holds if and only if $x \in \tilde{A}$. Since $x \notin A$, the event $x \in \tilde{A}$ is a false positive of $\tilde{A}$, which occurs with probability ε . Therefore the false negative rate of $\tilde{A}$ with respect to A^c is ε . $\square$

Remark. Theorem 3.1 establishes that complementation maps positive Bernoulli sets ($\omega = 0$) to negative Bernoulli sets ($\varepsilon = 0$) and vice versa. $\triangle$

3.2 Union

We derive the false positive and false negative rates of the union $\tilde{A}_1 \cup \tilde{A}_2$ as a Bernoulli set approximating $A_1 \cup A_2$.

Theorem 3.2 (Union false positive rate). *The union $\tilde{A}_1 \cup \tilde{A}_2$ has false positive rate*

$$\varepsilon = 1 - (1 - \varepsilon_1)(1 - \varepsilon_2) \quad (3.1)$$

with respect to $A_1 \cup A_2$.

Proof. Let $x \notin A_1 \cup A_2$. Then $x \notin A_1$ and $x \notin A_2$, so x is a negative of both A_1 and A_2 . A false positive of the union occurs when $x \in \tilde{A}_1 \cup \tilde{A}_2$, i.e., when $x \in \tilde{A}_1$ or $x \in \tilde{A}_2$ (or both). By the independence of errors across the two Bernoulli sets (assumption 1),

$$\mathbb{P}(x \in \tilde{A}_1 \cup \tilde{A}_2 | x \notin A_1 \cup A_2) = 1 - \mathbb{P}(x \notin \tilde{A}_1 \cup \tilde{A}_2 | x \notin A_1 \cup A_2) \quad (a)$$

$$= 1 - \mathbb{P}(x \notin \tilde{A}_1 | x \notin A_1) \mathbb{P}(x \notin \tilde{A}_2 | x \notin A_2) \quad (b)$$

$$= 1 - (1 - \varepsilon_1)(1 - \varepsilon_2). \quad (c)$$

Since this probability is the same for every negative of $A_1 \cup A_2$, the false positive rate of the union is $\varepsilon = 1 - (1 - \varepsilon_1)(1 - \varepsilon_2)$. $\square$

Theorem 3.3 (Union false negative rate). *The union $\tilde{A}_1 \cup \tilde{A}_2$ has false negative rate*

$$\omega = w_1\omega_1(1 - \varepsilon_2) + w_2\omega_2(1 - \varepsilon_1) + w_3\omega_1\omega_2 \quad (3.2)$$

with respect to $A_1 \cup A_2$, where

$$w_1 = \frac{|A_1 \setminus A_2|}{|A_1 \cup A_2|}, \quad w_2 = \frac{|A_2 \setminus A_1|}{|A_1 \cup A_2|}, \quad w_3 = \frac{|A_1 \cap A_2|}{|A_1 \cup A_2|}. \quad (3.3)$$

Proof. A false negative of the union occurs when an element $x \in A_1 \cup A_2$ satisfies $x \notin \tilde{A}_1 \cup \tilde{A}_2$, i.e., $x \notin \tilde{A}_1$ and $x \notin \tilde{A}_2$. We partition the positives $A_1 \cup A_2$ into three disjoint regions:

- (i) $A_1 \setminus A_2$: elements in A_1 only,
- (ii) $A_2 \setminus A_1$: elements in A_2 only,
- (iii) $A_1 \cap A_2$: elements in both A_1 and A_2 .

For region (i), let $x \in A_1 \setminus A_2$. Then $x \in A_1$ and $x \notin A_2$. By independence,

$$P(x \notin \tilde{A}_1 \text{ and } x \notin \tilde{A}_2 | x \in A_1, x \notin A_2) = \omega_1(1 - \varepsilon_2). \quad (\text{a})$$

For region (ii), let $x \in A_2 \setminus A_1$. Then $x \notin A_1$ and $x \in A_2$. By independence,

$$P(x \notin \tilde{A}_1 \text{ and } x \notin \tilde{A}_2 | x \notin A_1, x \in A_2) = (1 - \varepsilon_1)\omega_2. \quad (\text{b})$$

For region (iii), let $x \in A_1 \cap A_2$. Then $x \in A_1$ and $x \in A_2$. By independence,

$$P(x \notin \tilde{A}_1 \text{ and } x \notin \tilde{A}_2 | x \in A_1, x \in A_2) = \omega_1\omega_2. \quad (\text{c})$$

By the law of total probability, weighting each region by its proportion of $|A_1 \cup A_2|$,

$$\omega = w_1\omega_1(1 - \varepsilon_2) + w_2\omega_2(1 - \varepsilon_1) + w_3\omega_1\omega_2, \quad (\text{d})$$

where w_1 , w_2 , and w_3 are as defined in eq. (3.3). $\square$

Corollary 3.3.1 (Union of positive Bernoulli sets). *If $\tilde{A}_1$ and $\tilde{A}_2$ are positive Bernoulli sets ($\omega_1 = \omega_2 = 0$), then $\tilde{A}_1 \cup \tilde{A}_2$ is a positive Bernoulli set with*

$$\varepsilon = \varepsilon_1 + \varepsilon_2 - \varepsilon_1\varepsilon_2 \quad \text{and} \quad \omega = 0. \quad (\text{3.4})$$

Corollary 3.3.2 (Union of negative Bernoulli sets). *If $\tilde{A}_1$ and $\tilde{A}_2$ are negative Bernoulli sets ($\varepsilon_1 = \varepsilon_2 = 0$), then $\tilde{A}_1 \cup \tilde{A}_2$ is a negative Bernoulli set with*

$$\varepsilon = 0 \quad \text{and} \quad \omega = w_1\omega_1 + w_2\omega_2 + w_3\omega_1\omega_2, \quad (\text{3.5})$$

where w_1 , w_2 , w_3 are as in eq. (3.3).

3.3 Intersection

We now derive the error rates of the intersection $\tilde{A}_1 \cap \tilde{A}_2$ as a Bernoulli set approximating $A_1 \cap A_2$.

Theorem 3.4 (Intersection false negative rate). *The intersection $\tilde{A}_1 \cap \tilde{A}_2$ has false negative rate*

$$\omega = 1 - (1 - \omega_1)(1 - \omega_2) \quad (\text{3.6})$$

with respect to $A_1 \cap A_2$.

Proof. Let $x \in A_1 \cap A_2$. Then $x \in A_1$ and $x \in A_2$. A false negative of the intersection occurs when $x \notin \tilde{A}_1 \cap \tilde{A}_2$, i.e., when $x \notin \tilde{A}_1$ or $x \notin \tilde{A}_2$ (or both). By the independence of errors,

$$P(x \notin \tilde{A}_1 \cap \tilde{A}_2 | x \in A_1 \cap A_2) = 1 - P(x \in \tilde{A}_1 \cap \tilde{A}_2 | x \in A_1 \cap A_2) \quad (\text{a})$$

$$= 1 - P(x \in \tilde{A}_1 | x \in A_1) P(x \in \tilde{A}_2 | x \in A_2) \quad (\text{b})$$

$$= 1 - (1 - \omega_1)(1 - \omega_2). \quad (\text{c})$$

Since this probability is the same for every positive of $A_1 \cap A_2$, the false negative rate is $\omega = 1 - (1 - \omega_1)(1 - \omega_2)$. $\square$

Theorem 3.5 (Intersection false positive rate). *The intersection $\tilde{A}_1 \cap \tilde{A}_2$ has false positive rate*

$$\varepsilon = w_1(1 - \omega_1)\varepsilon_2 + w_2\varepsilon_1(1 - \omega_2) + w_3\varepsilon_1\varepsilon_2 \quad (3.7)$$

with respect to $A_1 \cap A_2$, where

$$w_1 = \frac{|A_1 \setminus A_2|}{u - |A_1 \cap A_2|}, \quad w_2 = \frac{|A_2 \setminus A_1|}{u - |A_1 \cap A_2|}, \quad w_3 = \frac{|U \setminus (A_1 \cup A_2)|}{u - |A_1 \cap A_2|}. \quad (3.8)$$

Proof. A false positive of the intersection occurs when an element $x \notin A_1 \cap A_2$ satisfies $x \in \tilde{A}_1 \cap \tilde{A}_2$, i.e., $x \in \tilde{A}_1$ and $x \in \tilde{A}_2$. We partition the negatives of $A_1 \cap A_2$ (the set $U \setminus (A_1 \cap A_2)$) into three disjoint regions:

- (i) $A_1 \setminus A_2$: elements in A_1 but not A_2 ,
- (ii) $A_2 \setminus A_1$: elements in A_2 but not A_1 ,
- (iii) $U \setminus (A_1 \cup A_2)$: elements in neither A_1 nor A_2 .

For region (i), let $x \in A_1 \setminus A_2$. Then $x \in A_1$ and $x \notin A_2$. By independence,

$$P(x \in \tilde{A}_1 \text{ and } x \in \tilde{A}_2 | x \in A_1, x \notin A_2) = (1 - \omega_1)\varepsilon_2. \quad (a)$$

For region (ii), let $x \in A_2 \setminus A_1$. Then $x \notin A_1$ and $x \in A_2$. By independence,

$$P(x \in \tilde{A}_1 \text{ and } x \in \tilde{A}_2 | x \notin A_1, x \in A_2) = \varepsilon_1(1 - \omega_2). \quad (b)$$

For region (iii), let $x \in U \setminus (A_1 \cup A_2)$. Then $x \notin A_1$ and $x \notin A_2$. By independence,

$$P(x \in \tilde{A}_1 \text{ and } x \in \tilde{A}_2 | x \notin A_1, x \notin A_2) = \varepsilon_1\varepsilon_2. \quad (c)$$

By the law of total probability, weighting by the proportion of $|U \setminus (A_1 \cap A_2)|$ contributed by each region,

$$\varepsilon = w_1(1 - \omega_1)\varepsilon_2 + w_2\varepsilon_1(1 - \omega_2) + w_3\varepsilon_1\varepsilon_2, \quad (d)$$

where w_1, w_2, w_3 are as in eq. (3.8). $\square$

Corollary 3.5.1 (Intersection of positive Bernoulli sets). *If $\tilde{A}_1$ and $\tilde{A}_2$ are positive Bernoulli sets ($\omega_1 = \omega_2 = 0$), then $\tilde{A}_1 \cap \tilde{A}_2$ is a positive Bernoulli set with*

$$\varepsilon = w_1\varepsilon_2 + w_2\varepsilon_1 + w_3\varepsilon_1\varepsilon_2 \quad \text{and} \quad \omega = 0, \quad (3.9)$$

where w_1, w_2, w_3 are as in eq. (3.8).

Corollary 3.5.2 (Intersection of negative Bernoulli sets). *If $\tilde{A}_1$ and $\tilde{A}_2$ are negative Bernoulli sets ($\varepsilon_1 = \varepsilon_2 = 0$), then $\tilde{A}_1 \cap \tilde{A}_2$ is a negative Bernoulli set with*

$$\varepsilon = 0 \quad \text{and} \quad \omega = \omega_1 + \omega_2 - \omega_1\omega_2. \quad (3.10)$$

3.4 Set difference

The set difference $A_1 \setminus A_2 = A_1 \cap A_2^c$ may be treated as an intersection of $\tilde{A}_1$ with $\overline{\tilde{A}_2}$. By theorem 3.1, $\tilde{A}_2$ has false positive rate ω_2 and false negative rate ε_2 with respect to A_2^c . Substituting these rates into the intersection formulas yields the following theorem.

Theorem 3.6 (Set difference error rates). *The set difference $\tilde{A}_1 \setminus \tilde{A}_2 = \tilde{A}_1 \cap \overline{\tilde{A}_2}$ has error rates*

$$\varepsilon = w_1(1 - \omega_1)\omega_2 + w_2\varepsilon_1(1 - \varepsilon_2) + w_3\varepsilon_1\omega_2, \quad (3.11)$$

$$\omega = 1 - (1 - \omega_1)(1 - \varepsilon_2) \quad (3.12)$$

with respect to $A_1 \setminus A_2$, where

$$w_1 = \frac{|A_1 \cap A_2|}{u - |A_1 \setminus A_2|}, \quad w_2 = \frac{|U \setminus (A_1 \cup A_2)|}{u - |A_1 \setminus A_2|}, \quad w_3 = \frac{|A_2 \setminus A_1|}{u - |A_1 \setminus A_2|}. \quad (3.13)$$

Proof. Write $\tilde{A}_1 \setminus \tilde{A}_2 = \tilde{A}_1 \cap \overline{\tilde{A}_2}$. By theorem 3.1, $\overline{\tilde{A}_2}$ approximates A_2^c with false positive rate ω_2 and false negative rate ε_2 . The objective set for the difference is $A_1 \setminus A_2 = A_1 \cap A_2^c$.

For the false negative rate, apply theorem 3.4 to the intersection of $\tilde{A}_1$ (FNR ω_1) and $\overline{\tilde{A}_2}$ (FNR ε_2):

$$\omega = 1 - (1 - \omega_1)(1 - \varepsilon_2). \quad (a)$$

For the false positive rate, we partition the negatives of $A_1 \cap A_2^c$ (the set $U \setminus (A_1 \setminus A_2)$) into three disjoint regions, mirroring the structure of theorem 3.5:

- (i) $A_1 \cap A_2$: here $x \in A_1$ and $x \in A_2$, so $x \in \tilde{A}_1$ with probability $1 - \omega_1$ and $x \in \overline{\tilde{A}_2}$ (i.e., $x \notin \tilde{A}_2$) with probability ω_2 . The contribution is $(1 - \omega_1)\omega_2$.
- (ii) $U \setminus (A_1 \cup A_2)$: here $x \notin A_1$ and $x \notin A_2$, so $x \in \tilde{A}_1$ with probability ε_1 and $x \in \overline{\tilde{A}_2}$ with probability $1 - \varepsilon_2$. The contribution is $\varepsilon_1(1 - \varepsilon_2)$.
- (iii) $A_2 \setminus A_1$: here $x \notin A_1$ and $x \in A_2$, so $x \in \tilde{A}_1$ with probability ε_1 and $x \in \overline{\tilde{A}_2}$ with probability ω_2 . The contribution is $\varepsilon_1\omega_2$.

By the law of total probability, weighting by the proportions w_1 , w_2 , and w_3 as defined in eq. (3.13),

$$\varepsilon = w_1(1 - \omega_1)\omega_2 + w_2\varepsilon_1(1 - \varepsilon_2) + w_3\varepsilon_1\omega_2. \quad (b)$$

□

Remark. The false negative rate of the set difference $\omega = 1 - (1 - \omega_1)(1 - \varepsilon_2)$ shows that even if $\tilde{A}_1$ has no false negatives ($\omega_1 = 0$), a nonzero false positive rate in $\tilde{A}_2$ induces false negatives in the difference, since elements of $A_1 \setminus A_2$ that are false positives of $\tilde{A}_2$ will be erroneously excluded. $\triangle$

3.5 Summary of error rates

Table 1 summarizes the error rates derived in the preceding subsections.

Remark (Unknown partition sizes). The partition weights w_1, w_2, w_3 require knowledge of the objective set cardinalities $|A_1|$, $|A_2|$, and $|A_1 \cap A_2|$, which are typically unknown in practice. Three approaches handle this: (a) if only upper bounds on $|A_i|$ are available, section 5 provides interval-valued rates; (b) worst-case bounds are obtained by optimizing the weights over the feasible region $w_1 + w_2 + w_3 = 1$, $w_i \geq 0$; (c) the cardinalities may be estimated from the approximate sets themselves, e.g., $|\tilde{A}_1 \cap \tilde{A}_2|$ is a biased estimator of $|A_1 \cap A_2|$ with computable bias from the error rates. $\triangle$

Table 1: Error rates of set-theoretic operations on Bernoulli sets. The partition weights w_1, w_2, w_3 are operation-dependent; see eqs. (3.3), (3.8) and (3.13) for their precise definitions.

Operation	FPR ε	FNR ω
$\tilde{A}_1$	ω_1	ε_1
$\tilde{A}_1 \cup \tilde{A}_2$	$1 - (1 - \varepsilon_1)(1 - \varepsilon_2)$	$w_1\omega_1(1 - \varepsilon_2) + w_2\omega_2(1 - \varepsilon_1) + w_3\omega_1\omega_2$
$\tilde{A}_1 \cap \tilde{A}_2$	$w_1(1 - \omega_1)\varepsilon_2 + w_2\varepsilon_1(1 - \omega_2) + w_3\varepsilon_1\varepsilon_2$	$1 - (1 - \omega_1)(1 - \omega_2)$
$\tilde{A}_1 \setminus \tilde{A}_2$	$w_1(1 - \omega_1)\omega_2 + w_2\varepsilon_1(1 - \varepsilon_2) + w_3\varepsilon_1\omega_2$	$1 - (1 - \omega_1)(1 - \varepsilon_2)$

Remark (Model order of composed sets). *The union and intersection formulas partition the relevant elements into regions with distinct per-element error probabilities. For instance, the union FNR assigns probability $\omega_1(1 - \varepsilon_2)$ to elements in $A_1 \setminus A_2$ but $\omega_1\omega_2$ to elements in $A_1 \cap A_2$. The result is therefore a higher-order Bernoulli set (definition 2.1) whose order equals the number of distinct partition blocks. The weighted-average rates in table 1 give the marginal error rates over all positives (or negatives), collapsing the partition structure into a single summary statistic.* $\triangle$

Remark (Parametric parsimony of composed sets). *The higher-order structure might suggest a proliferation of parameters. A general fourth-order channel on 4 observed symbols has $4 \times 3 = 12$ free parameters. However, element-wise independence (axiom 1) forces the joint transition matrix to factor as a Kronecker product of per-set 2×2 channels [1], so the union of two second-order Bernoulli sets requires only 4 parameters ($\varepsilon_1, \tau_1, \varepsilon_2, \tau_2$), not 12. More generally, composing m independent second-order Bernoulli sets yields a model of order up to 2^m on an alphabet of 2^m observed symbols, but the parameter count grows linearly as $2m$ rather than as $2^m(2^m - 1)$. This Kronecker structure is precisely what makes the closed-form composition formulas in table 1 possible: each entry is a polynomial in the $2m$ per-set rates.* $\triangle$

Example 1 (Numerical illustration of union error rates) *Let $|U| = 1000$, $|A_1| = 100$, $|A_2| = 80$, and $|A_1 \cap A_2| = 30$. Then $|A_1 \cup A_2| = 100 + 80 - 30 = 150$ and the partition weights for the union (eq. (3.3)) are*

$$w_1 = \frac{70}{150} \approx 0.467, \quad w_2 = \frac{50}{150} \approx 0.333, \quad w_3 = \frac{30}{150} = 0.200. \quad (\text{a})$$

Suppose $\varepsilon_1 = 0.01$, $\varepsilon_2 = 0.02$, $\omega_1 = 0.05$, and $\omega_2 = 0.03$. By theorem 3.2, the union FPR is

$$\varepsilon = 1 - (1 - 0.01)(1 - 0.02) = 1 - 0.99 \times 0.98 = 0.0298. \quad (\text{b})$$

By theorem 3.3, the union FNR is

$$\begin{aligned} \omega &\approx 0.467 \times 0.05 \times (1 - 0.02) + 0.333 \times 0.03 \times (1 - 0.01) + 0.200 \times 0.05 \times 0.03 \\ &\approx 0.02288 + 0.00990 + 0.00030 \approx 0.03307. \end{aligned} \quad (\text{c})$$

Thus $\tilde{A}_1 \cup \tilde{A}_2$ is a Bernoulli set approximating $A_1 \cup A_2$ with FPR ≈ 0.030 and FNR ≈ 0.033 .

Several structural observations follow from the table.

The union and intersection formulas exhibit a duality: the false positive rate of the union has the same functional form as the false negative rate of the intersection, and vice versa. This duality

Figure 1: Union false positive rate $\varepsilon = 1 - (1 - \varepsilon_1)(1 - \varepsilon_2)$ as a function of ε_2 for several fixed values of ε_1 . The thin dashed gray line shows the additive approximation $\varepsilon_1 + \varepsilon_2$ for $\varepsilon_1 = 0.01$; for small rates, the union FPR is nearly additive, but the product term $\varepsilon_1\varepsilon_2$ becomes significant as rates grow. By De Morgan duality, the intersection FNR has the same functional form with ω_i replacing ε_i .

reflects De Morgan's laws: $A_1 \cup A_2 = \overline{\overline{A_1} \cap \overline{A_2}}$, so that the union may be realized by complementing both operands, intersecting, and complementing the result. By theorem 3.1, each complementation exchanges the roles of ε and ω , producing the observed symmetry.

3.6 Closure properties

The error rates in table 1 reveal that certain classes of Bernoulli sets are closed under specific operations.

Theorem 3.7 (Closure of positive Bernoulli sets under intersection). *If $\tilde{A}_1$ and $\tilde{A}_2$ are positive Bernoulli sets, then $\tilde{A}_1 \cap \tilde{A}_2$ is a positive Bernoulli set.*

Proof. By corollary 3.5.1, when $\omega_1 = \omega_2 = 0$, the intersection has $\omega = 0$ and $\varepsilon = w_1\varepsilon_2 + w_2\varepsilon_1 + w_3\varepsilon_1\varepsilon_2 \geq 0$. Since $\omega = 0$, the result is a positive Bernoulli set. $\square$

Theorem 3.8 (Closure of negative Bernoulli sets under union). *If $\tilde{A}_1$ and $\tilde{A}_2$ are negative Bernoulli sets, then $\tilde{A}_1 \cup \tilde{A}_2$ is a negative Bernoulli set.*

Proof. By corollary 3.3.2, when $\varepsilon_1 = \varepsilon_2 = 0$, the union has $\varepsilon = 0$ and $\omega = w_1\omega_1 + w_2\omega_2 + w_3\omega_1\omega_2 \geq 0$. Since $\varepsilon = 0$, the result is a negative Bernoulli set. $\square$

Remark. Complement maps positive Bernoulli sets to negative Bernoulli sets and vice versa by theorem 3.1. In particular, the closure of positive sets under intersection and the closure of negative sets under union are dual statements: applying De Morgan's law and complementation converts one into the other. $\triangle$

These closure properties constrain which expressions over Bernoulli sets produce outputs that remain within the positive or negative class. The following grammar characterizes the set-theoretic

expressions that are guaranteed to produce a positive Bernoulli set (production $\langle \text{exp} \rangle$) or a negative Bernoulli set (production $\langle \text{nexp} \rangle$):

$$\langle \text{exp} \rangle ::= \langle \text{aset} \rangle \mid \langle \text{exp} \rangle \cup \langle \text{exp} \rangle \mid \langle \text{exp} \rangle \cap \langle \text{exp} \rangle \mid \overline{\langle \text{nexp} \rangle} \quad (3.14)$$

$$\langle \text{nexp} \rangle ::= \langle \text{naset} \rangle \mid \langle \text{nexp} \rangle \cup \langle \text{nexp} \rangle \mid \langle \text{nexp} \rangle \cap \langle \text{nexp} \rangle \mid \overline{\langle \text{exp} \rangle} \quad (3.15)$$

where $\langle \text{aset} \rangle$ denotes a positive Bernoulli set and $\langle \text{naset} \rangle$ denotes a negative Bernoulli set.

The grammar is justified as follows. A union of positive Bernoulli sets is positive by corollary 3.3.1, and an intersection of positive sets is positive by theorem 3.7; both productions are therefore included. Since $A_1 \cap A_2 = \overline{\overline{A_1} \cup \overline{A_2}}$, the intersection of two positive sets may be expressed as the complement of a union of two negative sets (via theorem 3.1), which by theorem 3.8 is negative, and whose complement is therefore positive. The dual argument applies for the $\langle \text{nexp} \rangle$ production.

3.7 Asymptotic behavior of composed error rates

The error-rate formulas above determine the *expected* rates for composed approximate sets. Since these composed rates inherit the Bernoulli structure from their operands, the asymptotic normal approximation of [4] applies.

For example, the true negative rate of the union $\tilde{A}_1 \cup \tilde{A}_2$ has the asymptotic distribution

$$\mathcal{N}_n \sim \mathcal{N}\left(\eta_1\eta_2, \frac{\eta_1\eta_2(1-\eta_1\eta_2)}{n}\right), \quad (3.16)$$

where $n = u - |A_1 \cup A_2|$ is the number of negatives. As $n \rightarrow \infty$, the distribution converges in probability to $\eta_1\eta_2$.

Remark (Convergence of intersections of positive approximate sets). *Consider independent positive approximate sets $A_{\varepsilon_1}^+, \dots, A_{\varepsilon_k}^+$ of the same objective set. As $k \rightarrow \infty$, $\bigcap_{i=1}^k A_{\varepsilon_i}^+$ converges almost surely to A , since each negative element survives with probability $\prod_{i=1}^k \varepsilon_i \rightarrow 0$. Dually, for negative approximate sets, $\bigcup_{i=1}^k A_{\omega_i}^-$ converges almost surely to A .* $\triangle$

Remark (Monoidal structure). *The results above show that the collection of Bernoulli sets over U is closed under union and intersection (with computable output rates). Since these operations inherit associativity and commutativity from the powerset 2^U , Bernoulli sets form a commutative semigroup under each. If the degenerate-case axiom is adopted— $P(\emptyset^\pm = \emptyset) = 1$ and, dually, $P(U^\pm = U) = 1$ (see [4])—then $\emptyset$ and U serve as identity elements, yielding commutative monoids under union and intersection respectively. This is useful in practice: the n -ary union $\bigcup_{i=1}^n A_i^\pm$ is precisely the monoidal fold, requiring only an associative operation and an identity element.* $\triangle$

4 Relational probabilities

The relational *member-of* predicate $\in: U \times 2^U \rightarrow \{0, 1\}$ is the set-indicator function, or the *membership* predicate, which is true if x is a member of the set A and false otherwise. By proposition 2.1, given $x \in A$, $x \in \tilde{A}_\tau^\varepsilon$ with probability τ and given $x \notin A$, $x \in \tilde{A}_\tau^\varepsilon$ with probability ε . These probabilities are axiomatic in the second-order random approximate set model.

Other kinds of relational predicates are functions of the *member-of* predicate, in particular the subset $\subseteq: 2^U \times 2^U \rightarrow \{0, 1\}$, equality $=: 2^U \times 2^U \rightarrow \{0, 1\}$, and proper subset $\subset: 2^U \times 2^U \rightarrow \{0, 1\}$

predicates respectively defined as (where $[\phi]$ denotes the Iverson bracket: 1 if ϕ is true, 0 otherwise)

$$A \subseteq B = \prod_{x \in A} [x \in B], \quad (4.1)$$

$$A = B = (A \subseteq B) \wedge (B \subseteq A), \text{ and} \quad (4.2)$$

$$A \subset B = (A \neq B) \wedge (A \subseteq B) \quad (4.3)$$

where complementary relations are naturally given by complements, e.g., $A \neq B = 1 - (A = B)$.

Theorem 4.1. *Given $X \subseteq Y$, $\tilde{X} \subseteq \tilde{Y}$ with probability*

$$(1 - \tau_1 \omega_2)^{|X|} (1 - \varepsilon_1 \omega_2)^{|Y| - |X|} (1 - \varepsilon_1 \eta_2)^{|U| - |Y|}, \quad (4.4)$$

where $\tilde{X}$ has a false positive rate ε_1 and a true positive rate τ_1 and $\tilde{Y}$ has a false positive rate ε_2 and true positive rate τ_2 .

Proof. $\tilde{X} \subseteq \tilde{Y}$ holds if and only if, for every element $j \in U$, $j \in \tilde{X}$ implies $j \in \tilde{Y}$. Equivalently, the event $j \in \tilde{X} \wedge j \notin \tilde{Y}$ must not occur for any j . By element-wise independence and cross-set independence (assumption 1), the probability is

$$\gamma = \prod_{j=1}^u \left(1 - \mathbb{P}(j \in \tilde{X}) \mathbb{P}(j \notin \tilde{Y}) \right), \quad (a)$$

where the probabilities are conditioned on membership in X and Y respectively. Since $X \subseteq Y$, the universal set partitions into three blocks:

1. X : elements in both X and Y ($|X|$ elements),
2. $Y \setminus X$: elements in Y but not X ($|Y| - |X|$ elements),
3. $U \setminus Y$: elements in neither ($|U| - |Y|$ elements).

Substituting the error rates for each block:

- Block 1: $\mathbb{P}(j \in \tilde{X}) = \tau_1$ and $\mathbb{P}(j \notin \tilde{Y}) = \omega_2$.
- Block 2: $\mathbb{P}(j \in \tilde{X}) = \varepsilon_1$ and $\mathbb{P}(j \notin \tilde{Y}) = \omega_2$.
- Block 3: $\mathbb{P}(j \in \tilde{X}) = \varepsilon_1$ and $\mathbb{P}(j \notin \tilde{Y}) = \eta_2$.

Since each block contributes a constant factor per element, the product reduces to

$$\gamma = (1 - \tau_1 \omega_2)^{|X|} (1 - \varepsilon_1 \omega_2)^{|Y| - |X|} (1 - \varepsilon_1 \eta_2)^{|U| - |Y|}. \quad (b)$$

□

Corollary 4.1.1. *Given $X = Y$, $\tilde{X}[\varepsilon_1][\tau_1] = \tilde{Y}[\varepsilon_2][\tau_2]$ with probability*

$$(\tau_1 \tau_2 + \omega_1 \omega_2)^{|X|} (\varepsilon_1 \varepsilon_2 + \eta_1 \eta_2)^{|U| - |X|}. \quad (4.5)$$

Proof. $\tilde{X} = \tilde{Y}$ holds if and only if $\mathbf{1}_{\tilde{X}}(j) = \mathbf{1}_{\tilde{Y}}(j)$ for every $j \in U$. By element-wise independence across elements, the probability is $\prod_{j \in U} P(\mathbf{1}_{\tilde{X}}(j) = \mathbf{1}_{\tilde{Y}}(j))$. Since $X = Y$, the universe partitions into two blocks:

- $j \in X$: both indicators are independent Bernoulli trials with success probabilities τ_1 and τ_2 respectively, so they agree with probability $\tau_1\tau_2 + \omega_1\omega_2$.
- $j \notin X$: both indicators have success probabilities ε_1 and ε_2 , so they agree with probability $\varepsilon_1\varepsilon_2 + \eta_1\eta_2$.

Since each block contributes a constant factor per element, the product reduces to the stated formula. $\square$

Corollary 4.1.2. *Given $X = Y$, $\tilde{X}_\tau^\varepsilon = \tilde{Y}_\tau^\varepsilon$ with probability*

$$\left(\tau^2 + \omega^2\right)^{|X|} \left(\varepsilon^2 + \eta^2\right)^{|U|-|X|}. \quad (4.6)$$

Proof. Set $\varepsilon_1 = \varepsilon_2 = \varepsilon$ and $\tau_1 = \tau_2 = \tau$ in the preceding corollary: the positive-block factor becomes $\tau^2 + \omega^2$ and the negative-block factor becomes $\varepsilon^2 + \eta^2$. $\square$

Corollary 4.1.3. *Given $X \subseteq Y$, $\tilde{X}[+][\tau_1] \subseteq \tilde{Y}[+][\tau_2]$ with probability*

$$(1 - \tau_1\omega_2)^{|X|}. \quad (4.7)$$

Proof. For positive approximate sets, $\varepsilon_1 = \varepsilon_2 = 0$, so the second and third factors of the subset theorem reduce to 1 (each equals 1^n). Only the first factor remains. Since $\omega_2 = 1 - \tau_2$, this gives $(1 - \tau_1\omega_2)^{|X|}$. $\square$

Corollary 4.1.4. *Over an infinite universal set, the probability that two second-order random approximate sets realize the same value is 0.*

Proof. Each factor in the equality probability is strictly less than 1 when $\varepsilon, \tau \in (0, 1)$. As $|U| \rightarrow \infty$, the product of such factors raised to powers growing with $|U|$ tends to 0. $\square$

Corollary 4.1.5. *Over an infinite universal set, the probability that a second-order random approximate set realizes a value that is a subset of another realization of a second-order random approximate set is 0.*

Proof. The third factor of the subset probability, $(1 - \varepsilon_1\eta_2)^{|U|-|Y|}$, tends to 0 as $|U| \rightarrow \infty$ whenever $\varepsilon_1\eta_2 > 0$. $\square$

5 Interval arithmetic for uncertain rates

In practice, the expected false positive and true positive rates may not be known exactly. This section develops an *interval arithmetic* approach: each uncertain rate is represented by an interval guaranteed to contain the true value, and the error-rate formulas of section 3 are evaluated over these intervals to produce guaranteed bounds on the output rates.

Definition 5.1. *An interval is a convex set of real numbers. We denote by $[\underline{x}, \bar{x}]$ an interval with a lower-bound $\underline{x}$ and an upper-bound $\bar{x}$.*

A confidence interval may be specified in interval notation. Here, however, we consider an algebra for interval arithmetic and put it to use quantifying our ignorance about the distribution of parameters after, for instance, a union operation.

The error-rate formulas of section 3 depend upon the false positive and false negative rates being *known*. Any parameters that are not known with certainty may be replaced by intervals that (are assumed to) contain the true value. As a consequence, the output error rate will also be an interval.

Maximum uncertainty is when the parameter value is in the interval $[0, 1]$, e.g., $[\varepsilon] = [0, 1]$, and *minimum* uncertainty is when the parameter is some value in the degenerate interval $[x, x]$, e.g., $[\varepsilon] = [.2, .2]$. The more certain—the smaller the width of the intervals—the more certain the output rate.

When using interval arithmetic, the *dependency problem* can lead to overly pessimistic bounds. In our case, the formulae are simple enough to ensure dependencies are satisfied. The following example illustrates the approach for the union false positive rate.

Example 2 Suppose two approximate sets have false positive rates known only to lie in $[\varepsilon_1]$ and $[\varepsilon_2]$ respectively. The union FPR formula (theorem 3.2) is $\varepsilon = 1 - (1 - \varepsilon_1)(1 - \varepsilon_2)$, which is monotonically increasing in both ε_1 and ε_2 . Evaluating at the endpoints yields guaranteed bounds:

$$[\varepsilon] = \left[1 - (1 - \underline{\varepsilon}_1)(1 - \underline{\varepsilon}_2), 1 - (1 - \bar{\varepsilon}_1)(1 - \bar{\varepsilon}_2) \right]. \quad (\text{a})$$

For instance, if $[\varepsilon_1] = [0.01, 0.05]$ and $[\varepsilon_2] = [0.02, 0.08]$, then $[\varepsilon] = [0.0298, 0.126]$.

We may not be interested in the *expected* value, but the smallest set of values such that with probability $1 - \gamma$ the true rate realizes some value in the set, which is typically an *interval*, i.e., a confidence interval.

Intervals represent an uncertainty and they manifest themselves in two independent ways. The common notion of the *confidence interval* is a product of the probabilistic model, i.e., the realized true positive rate $\hat{\tau}$, which is normally centered around the expected true positive rate τ as discussed in [4]. We may use *interval arithmetic* and replace point values with interval values, point values being a degenerate case. Basic interval arithmetic is presented in [2]; the foundational treatment is due to Moore [3].

A set sampled from $\tilde{A}[\varepsilon][\tau]$ is an approximate set such that the $\gamma \cdot 100\%$ asymptotic confidence intervals for the realized false negative and false positive rates are respectively given by

$$[\omega] = \omega \pm \sqrt{\frac{\omega(1 - \omega)}{p}} \Phi^{-1} \left(\frac{1 + \gamma}{2} \right) \quad (5.1)$$

and

$$[\varepsilon] = \varepsilon \pm \sqrt{\frac{\varepsilon(1 - \varepsilon)}{n}} \Phi^{-1} \left(\frac{1 + \gamma}{2} \right), \quad (5.2)$$

where p and n are the number of positives and negatives respectively and Φ^{-1} is the inverse CDF of the standard normal (see eqs. (2.2) and (2.3)).

5.1 Interval propagation through set operations

The simple error-rate formulas—union FPR, intersection FNR, and complement—are monotonically increasing in each input rate. The weighted formulas (union FNR, intersection FPR, and set difference rates) have *mixed monotonicity*: they increase in same-type rates (ω in ω , ε in ε) and decrease in cross-type rates (ω in ε , ε in ω). Replacing point-valued rates with intervals and evaluating at the appropriate endpoints for each variable yields guaranteed bounds on the output rates.

Theorem 5.1 (Complement). *The complement of an approximate set with a false negative rate $[\omega]$ and false positive rate $[\varepsilon]$ is an approximate set with a false negative rate $[\varepsilon]$ and false positive rate $[\omega]$.*

Proof. Follows immediately from theorem 3.1: complementation swaps positives and negatives, so it swaps the false positive and false negative rates. Since the interval endpoints swap accordingly, the result holds. $\square$

Theorem 5.2 (Union). *Given two approximate sets with interval-valued rates $[\varepsilon_1]$, $[\omega_1]$ and $[\varepsilon_2]$, $[\omega_2]$, the union has interval-valued false positive rate*

$$[\varepsilon] = \left[1 - (1 - \underline{\varepsilon}_1)(1 - \underline{\varepsilon}_2), 1 - (1 - \bar{\varepsilon}_1)(1 - \bar{\varepsilon}_2) \right], \quad (5.3)$$

since the union FPR formula $\varepsilon = 1 - (1 - \varepsilon_1)(1 - \varepsilon_2)$ from theorem 3.2 is monotonically increasing in both ε_1 and ε_2 . Since the union FNR (eq. (3.2)) increases in ω_1, ω_2 and decreases in $\varepsilon_1, \varepsilon_2$, the upper bound is attained at $(\bar{\omega}_1, \bar{\omega}_2, \underline{\varepsilon}_1, \underline{\varepsilon}_2)$ and the lower bound at $(\underline{\omega}_1, \underline{\omega}_2, \bar{\varepsilon}_1, \bar{\varepsilon}_2)$.

Remark. *Intersection and set difference follow analogously: the intersection FNR has the same form as the union FPR (by the De Morgan duality noted in section 3.5), and the set difference is handled by substituting complemented intervals per theorem 5.1.* $\triangle$

6 Conclusion

We have shown that Bernoulli sets are closed under all four set-theoretic operations: complement, union, intersection, and set difference. Each operation yields a (possibly higher-order) Bernoulli set whose error rates are closed-form functions of the operand rates and set cardinalities. The resulting collection of Bernoulli sets forms commutative monoids under union and intersection, with the empty set and universal set serving as identity elements. Relational predicates—subset and equality—admit exact probability formulas that factorize element-wise. An interval arithmetic extension propagates uncertain rate parameters through set operations, yielding guaranteed bounds when parameters are only approximately known.

Practical implications. A practitioner building a system on Bloom filters need not re-derive the error analysis for each new combination of filters: the composition theorems of section 3 apply immediately, yielding closed-form error rates and confidence intervals for any set-theoretic expression.

Open problems. The partition weights w_1, w_2, w_3 in the set-operation formulas require knowledge of the objective set cardinalities, which are typically unknown (section 3.5). Developing principled estimators for these cardinalities from the approximate sets themselves, with quantified bias and variance, is a natural next step.

Companion papers. The Bernoulli set model, including the axioms, error-count distributions, asymptotic limits, confidence intervals, and higher-order composition theorem, is developed in [4]. The probability distributions of binary classification measures (positive predictive value, negative predictive value, accuracy, Youden’s J) are derived in [5]. The joint entropy of error counts and the information-theoretic space complexity lower bound are developed in [6].
